INTRODUCTION

Delayed facial palsy (DFP) is an uncommon complication after middle ear surgery; it occurs after >72 hours of an uneventful ear surgery [1]. Shea described this phenomenon as “five and a half day syndrome,” meaning that all his personal observations shared the same time lag from surgery. [2] DFP after stapedectomy is a very rare event (0.22%) [3]. Its incidence in the literature ranges between 0.07% and 1.4%. [4-6] While immediate facial palsy is easily explained by the use of local anesthetics (if transient) or by intraoperative severe surgical trauma (if permanent), many hypotheses have been proposed about the late facial nerve dysfunctions, including reactivation of a quiescent virus colonizing the nerve ganglion. According to Shea et al. [4] the most probable etio-pathogenetic mechanism for DFP is the activation of a latent herpesvirus in the geniculate ganglion, induced by mechanical stimulation or reactive inflammation of the facial nerve during middle ear surgery. This hypothesis has been supported by many other observations after otological surgical procedures [7-18] and preventive antiviral therapy has been proposed in patients with positive history to varicella zoster virus and herpes simplex virus 1 and 2. However, serological search of a viral etiology is often inconclusive, not always identifying which virus (HSV type 1, 2, or VZV) is involved; the proposed use of preventive therapy with antivirals in all stapedectomy patients is still debated and often not applied in clinical practice [4-7].

The purpose of this work is to review the relevant literature on DFP after stapedectomy, aiming at properly assessing the viral etiology and at identifying factors that might influence the prognosis or the recovery time or the choice of therapies, and describe a very unusual case of DFP characterized by VZV reactivation showed by the eruption of typical RH lesions.

MATERIALS and METHODS

A PubMed search encompassing all publications over the last 40 years was initially performed searching for “facial palsy OR paralysis OR paresis” AND “stapedectomy OR stapedotomy OR stapes surgery” using Boolean combinations; Further, the terms “delayed OR late” were added to the search. The date of last search was 18th March 2018. After screening all the articles abstracts, full-text works pertinent
to DFP after stapedectomy were retrieved and analytically reviewed. Another PubMed search was conducted by searching for the “revision” stapes surgery utilizing the same Boolean combinations: the resulting abstracts were screened for relevance to account for all published cases of DFP. Chronology of onset of remission of the postoperative facial palsy, operated side, age and sex of patients, predisposing factors, surgical technique and tools, intraoperative observations, serological assays, pharmacological therapies, and facial outcomes were looked for in each article and tabulated on a Microsoft Excel spreadsheet. The heterogeneity of case-reports data set and case-series data set did not allow performing a pooled extraction analysis or meta-analysis regarding the effects of surgical procedures and DFP postoperative treatment. No language restrictions were applied and systematic review of the literature has been summarized. In addition to the literature search, a case of DFP with unique features of VZV infection in an adult who had undergone stapedectomy is described and the findings are compared with similar reports in scientific publications. The House–Brackmann (H-B) facial nerve grading system (1985) was used to evaluate the facial function in patients with DFP after stapedectomy and at the end of the recovery period.

All procedures contributing to this work comply with the ethical standards of the relevant national and institutional guidelines on human experimentation (IRB 2016) and with the Helsinki Declaration of 1975, as revised in 2008. The patient has given written consent for publication.

Statistical Analysis
Descriptive statistical analysis was performed using Statistical Packages for the Social Sciences (SPSS) software for Mac version 22.0 (IBM Corp., Armonk, NY, USA).

RESULTS
Till date, 48 cases of DFP after stapes surgery have been described in the literature, including the present case; 33 of them occurred after stapedectomy and 14 after laser stapedoplasty. DFP were evenly distributed across age and sex and usually develops rapidly into complete palsy after few hours of onset. (Table 1) In all reported cases, the stapes surgeries were uneventful. In the literature, the onset time of DFP varies from 4 to 20 days after surgery (8.5±3.5 days). Interestingly, no specific macroscopic or otomicroscopic signs are usually observed neither reported in cases series; conversely, typical RH is characterized by the typical appearance of VZV vesicles in the conchal area and at the entrance of the external auditory meatus, facial palsy, hearing loss, and intense pain. The association of increased anti-HSV 1-2 and VZV IgM with typical RH syndrome with ear pain and presence of vesicles at the entrance of the ear canal represent the most reliable indicators of VZV reactivation. However, after uncomplicated stapedectomy reported in the literature, typical RH was also absent in patients whose serologic tests proved positive. The recovery time after DFP onset ranges from 2 to 270 days (mean 45±43 days) with I-II final H-B grade in all the reported cases, regardless of the therapies.

A retrospective review of all subsequent operated patients during the last decade has been currently obtained for the purpose of this study. In our casistics, 1253 stapedectomies were personally performed by the same operator between January 1992 and May 2016, using the same conventional technique of footplate fenestration (0.4 to 0.6 mm calibrated hole) with a microdrill without connective tissue interposition. In the entire personal series, DFP occurred only in one patient, accounting for an incidence of 0.08%.

This patient was a 51-year-old female, admitted for bilateral otosclerosis, who underwent right stapedotomy under local anesthesia and interposition of a standard platinum-fluoroplastic piston (Audio Technologies, Piacenza, Italy) measuring 0.6 × 4.5 mm through a 0.7 mm platinitomy hole obtained using a microdrill. Preoperative pure tone audiometry showed bilateral up-sloping conductive hearing loss with a pure tone average of 58.7 dB HL in the right ear and 48.6 in the left; the mean air-bone gap (ABG) was 40 dB HL and 35.2 dB HL respectively. The middle ear anatomy was normal; in particular, the Fallopian canal was intact. Chorda tympani nerve was not stretched neither manipulated; no intraoperative complications were encountered.

The postoperative course was uneventful, except for slight dizziness induced by head movements during the first 12 hours. She was discharged on the 1st postoperative day with prescription of 400 mg oral cefixime q.i.d. and local instillation ear drops (0.3% ofloxacin solution b.i.d.) for 5 days.

On the 12th postoperative day, the patient complained of intense pain in the right (operated) ear, which was only partially relieved by anti-inflammatory drugs. On the 15th day, she noticed facial paresis on the operated side. The paresis progressed to complete palsy (H-B grade VI) within 24 hours. Painful edema of the soft tissues of the outer ear canal was observed; the retroauricular skin was hyperemic. The patient had a positive history for chickenpox during childhood; she reported suffering of herpes labialis, once adult, due to sporadic reactivation of HSV type 1 and 2, which has been serologically proven in an occasion of a viral bout a few years earlier. Two days after the onset of facial palsy, elevated levels of specific anti-VZV IgG and IgM were observed by ELISA assay and complement fixation test.

Small vesicles with typical VZV morphology appeared two days after the onset of the palsy at the triangular fossa and on the medial surface of the tragus, extending to the conchal area and the external meatus during the next 48 hours (Figure 1).

Pharmacological treatment with acyclovir (800 mg oral administration, five times per day) was started on postoperative day 15 (at the onset of the paresis) and continued for 10 days; eardrops had already been discontinued one week earlier and were not reintroduced. The eardrum looked normalized at micro-otoscopy, except for residual mild hyperemia around the malleus handle and the pars flaccida; pure tone audiometry revealed significant improvement in the air-conducted hearing threshold with reduction of the ABG within 20 dB HL and no sensorineural deficits.

An electroneuronography (ENoG), obtained 6 days after the onset of the palsy, showed complete denervation and an 80% decrease in nerve conduction by nerve excitability test. An electromyographic (EMG) study of the facial musculature on the 24th day after the onset confirmed the absence of response to stimulation at the stylomastoid foramen.

*3 days before DFP onset; n.s. = not specified; n.p. = not performed
A surgical re-exploration of the middle ear was not deemed useful nor was the decompression of the Fallopian canal up to its labyrinthine segment through a combined approach, as proposed in the past by some authors [26].

Eight weeks later, the facial palsy gradually started to improve, and at six months, it had returned to H-B grade III. At that time, a control EMG showed a significant increase of active motor units of the VII nerve. The facial weakness further improved in the following 8
months, when it reached grade II, then stabilized with minimal resid-
ual dynamic dysfunction and slight oculo-oral synkinesis.

DISCUSSION

Typical RH was first described by James Ramsay Hunt in 1907; the
viruses can be reactivated during periods of generic temporary de-
pression of the immune system induced by physical or emotional
stress, concurrent bacterial or viral infections, neoplasms, mechanical
or surgical trauma, including local surgical stress. In 1972, Steffen
and Shelby firstly described an “Atypical RH Syndrome,” starting
with vague symptoms and without the typical vesicular eruption in
the concha (“Zoster sine herpete”). This clinical pattern is generally
extremely rare but it might proceed with the involvement of other
dermatomes or districts of the neck and face. To our knowledge,
this is the first case of DFP with typical RH syndrome after stapedecto-
my reported in the literature; the appearance of the pathognomonic
herpetic vesicles within few days after the onset of the palsy allowed
us to confirm unequivocally the pathogenetic role of VZV reactiva-
tion. In literature, RH with DFP has been reported only in two cases,
both after acoustic neuroma surgery. In particular, Gianoli et al.
described a case of DFP with typical RH after trans-labyrinthine re-
section of an acoustic neuroma: the herpetiform lesions appeared on
the ipsilateral ear canal and extended to the ipsilateral buccal mucosa;
anti-VZV antibodies were elevated.

In DFP, an isolated increase in serum anti-VZV IgG antibodies has been
reported in literature confirming the suspect a viral reactivation. However, because most patients with breakthrough VZV will have pre-
existing elevated IgG antibody titers to VZV, conventional IgG determi-
nations are of limited value unless measurements are performed both
during the acute and convalescent phase. Evidence of VZV-specific
IgM in serum indicates recent exposure to VZV but does not discrimi-
nate between primary infection, reinfection, and reactivation. Moreover, the absence of IgM antibody does not exclude a recent VZV expo-
sure because IgM antibodies are inconsistently observed even among
cases with PCR-confirmed infection by VZV and the most reliable and
sensitive laboratory method for confirming varicella is the detection
of VZV DNA in samples (vesicular swabs, scabs, and saliva) obtained
from skin lesions using PCR. Unfortunately, this examination is not
possible in DFP cases because typical RH is absent and none has been
reported data from saliva in the literature.

Furthermore, although the etiopathogenetic role of herpes virus re-
activation is controversial, serologic tests were obtained only in less
than half of the cases (21/48) of DFP reported in the literature. Even
positive history of recurrent labial HSV lesions or previous VZV infec-
tion, which is considered valuable anamnestic indicator, were often
underestimated or not even investigated.

Alternatively, the incidence of DFP after stapedectomy ranges be-
 tween 0.07% and 1.4% in the literature, corresponding to 1/450 to
1/1000 of operated ears. A higher incidence has been reported in
more limited series, (1.4%–37.5%), particularly those employing
lasers. Considering the possible reduction of natural immunity follow-
ing the mass VZV vaccination campaign, one might expect a recrudes-
cence of VZV after stapedectomy; instead, a relevant increase in the
incidence of DFP has not yet been observed.

When evident, typical conchal blebs of RH syndrome appear later
than the facial paresis; electrophysiological tests do not differenti-
ate post-surgical DFP from other types of facial paresis; and imag-
ing after uncomplicated stapedectomies with DFP is not conclusive,
although useful for possible medicolegal purposes to exclude iatro-
genic lesions. Thus, presence of specific anti-VZV IgG and IgM should
be checked for confirmation of etiology; special attention must be
paid to prodromal symptoms, such as unexplained late pain (acute
neuropathic otalgia).

In conclusion, “Zoster sine herpete” is the most frequent pattern re-
ported in literature and reactivation of VZV might be underestimated
in clinical practice because of the lack of typical RH in DFP after sta-
pedectomy.

Given the paucity of DFP, the universal preventive use of antivirals
in stapes surgery is not warranted, except for selected cases. For this
reason, the initial intense pain might indicate those cases who would
benefit from immediate administration of antivirals.
